This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the author guidelines.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the ethical guidelines, outlined in our author and reviewer resource centre, still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Temperature-dependent dynamics of NH$_3$-derived Cu species in the Cu-CHA SCR catalyst

Elisa Borfecchia$^a$, Chiara Negri$^a$, Kirill A. Lomachenko$^b$, Carlo Lambert$^{c,d}$, Ton V. W. Janssens$^e$, Gloria Berlier$^d$

The Cu-exchanged CHA zeolite (Cu-CHA) is a promising catalyst for the NH$_3$-assisted selective catalytic reduction (NH$_3$-SCR) of harmful nitrogen oxides (NO$_x$, $x = 1, 2$), combining high hydrothermal stability with a good performance in the 200-550 °C range. Despite many recent breakthroughs in the molecular-scale understanding of this catalyst, several open questions remain to ultimately unravel the NH$_3$-SCR mechanism across the operation-relevant temperature range. In this context, we apply in situ XAS and UV-Vis-NIR spectroscopy to assess the nature and thermal stability of NH$_3$-derived Cu-species in a commercial Cu-CHA deNO$_x$ catalyst. Both techniques evidence a fast and complete ‘solvation’ by NH$_3$ of the framework-coordinated Cu$^{I}$ and Cu$^{II}$ ions formed upon thermal activation of the catalyst. Our results confirm that NH$_3$ desorption at $T > 200$ °C is accompanied by Cu$^{I}$ → Cu$^{II}$ reduction phenomena, while the presence of pre-adsorbed NH$_3$ with gas-phase NO greatly enhances the reduction rate and efficiency. By applying state-of-the-art Multivariate Curve Resolution (MCR) analysis, we elaborate these insights in a quantitative picture of Cu-speciation during NH$_3$ temperature-programmed desorption (TPD) and surface reaction (TPSR) experiments. MCR analysis confirms recent theoretical predictions for the thermal stability of [Cu$^{I}$NH$_3$]$^+$ species and allows us to experimentally identify the framework-coordinated O$_{\text{fw}}$-Cu$^{II}$-NH$_3$ intermediate formed upon desorption of a NH$_3$ ligand from [Cu$^{II}$NH$_3$]$^+$.

1. Introduction

The road transport sector is one of the driving forces of EU economy and a key factor for keeping dynamic cities and urban networks, but it also represents one of the major air pollution sources, being the largest contributor to NO$_x$ emissions (39 % in the EU-28).$^1$ This represents a serious threat to human health (with related important costs for the EU economy) notwithstanding the strict Euro 6 regulations introduced in recent years (2014), which prescribe 80% reduction in NO$_x$ emissions.$^2$ A significant R&D activity has thus been focused in the last two decades to the development of stable and active catalysts to reduce NO$_x$ emission from diesel exhaust aftertreatment systems.$^3$ Metal exchanged zeolites have been readily identified for such application by the scientific community. However, the real breakthrough came from the discovery of the small pore chabazite framework (Cu-CHA) catalysts, which combine high hydrothermal stability with a good performance in the 200-550 °C range.$^4,5$ Cu ions, introduced in Cu-CHA by ion exchange as Cu$^{II}$, are able to reversibly change their oxidation state depending on activation conditions and presence of reactants.$^6,7$ In oxidizing conditions both Z[Cu$^{II}$] and Z$_2$Cu$^{II}$ species (where Z indicates a framework negative charge induced by the presence of framework Al atoms) are formed, with relative concentration depending on the sample Cu/Al and Si/Al ratios.$^8,9$ The possible presence of Z[Cu$^{II}$][O$^2$]$^-$$^+$ species was also recently put forward.$^7,10,11$ On the other hand, in inert/reducing conditions, ZCu$^{I}$ sites can be stabilized in 6- or 8-member rings (6MR and 8MR).$^9,12$ The NH$_3$-SCR reaction can be divided into two half-cycles. In the reduction part, Cu$^{II}$ ions are readily converted into Cu$^{I}$ in the presence of NO and NH$_3$, releasing the reaction products, N$_2$ and H$_2$O. The crucial step of the cycle is believed to be the re-oxidation of Cu$^{I}$ to Cu$^{II}$, involving the activation of O$_2$,$^8,13-16$ which is promoted by the presence of NO.$^{15}$ Most of the current literature is focused on this kinetically relevant half-cycle. For instance, Janssens et al. proposed copper(II) nitrates formed upon interaction of the catalyst with NO + O$_2$ as an important intermediate of the cycle.$^{13,17,18}$ The role of nitrates was debated by Marberger et al. on the basis of time-resolved X-ray absorption spectroscopy (XAS) experiments,$^{16}$ while other authors proposed the relevance of the nitrosium ion...
NO\(^+\),\(^{19}\) of a ‘nitrite route\(^{20}\) and of ammonium nitrate.\(^{21}\) A different point of view concerning the \(O_2\) activation step was recently proposed by Paolucci et al.,\(^{14}\) who highlighted the crucial role of the mobile [Cu\(\text{II}\)(NH\(_3\))\(_2\)]\(^+\) complexes formed upon interaction at 200 °C of Cu\(^{\text{II}}\) ions with the NO+NH\(_3\) mixture.\(^{13,22}\) The different kinetic regimes measured by many research groups on samples with high and low Cu loadings were thus explained by assuming the formation of active Cu\(\text{II}\)(NH\(_3\))\(_2\)-O\(_2\)-Cu\(\text{II}\)(NH\(_3\))\(_2\) pairs, which are favoured at Cu density above 0.2 Cu/1000 Å\(^3\).\(^{14}\) The effect of Al distribution on this mechanism has also been assessed by \textit{ab initio} molecular dynamics simulations.\(^{24}\)

Notwithstanding the importance of the re-oxidation step, many aspects of the chemistry taking place during the reduction half-cycle are still under investigation.\(^{22,25-27}\) As mentioned above, mobile [Cu\(\text{II}\)(NH\(_3\))\(_2\)]\(^+\) species are known to be present in NH\(_3\)-SCR conditions at low reaction temperatures,\(^{13,22,25}\) together with a fraction of ammonia-solvated Cu\(^{\text{II}}\) ions. These could be in the form of [Cu\(\text{II}\)(NH\(_3\))\(_4\)]\(^+\) or include an OH ligand resulting in [Cu\(\text{II}\)(NH\(_3\))(OH)]\(^+\) complexes.\(^{23}\) Notice that the discrimination between these two species is not straightforward with most characterization techniques. For instance, XAS, which is one of the most powerful technique to give a precise description of the metal ion coordination sphere, cannot precisely discriminate between O and N ligands.\(^{23}\) On the other hand, the [Cu\(\text{II}\)(NH\(_3\))\(_n\)]\(^+\) species, which are supposed to play a crucial role in the oxidation step, has been shown to be unstable above 250 °C in NH\(_3\)-SCR conditions, resulting in a significant fraction of framework-coordinated Cu\(^{\text{II}}\) ions.\(^{23}\) Thus, the reactivity of NH\(_3\) in Cu-CHA still presents interesting scientific aspects. For instance, Lezcano-Gonzales et al. showed that NH\(_3\) is also adsorbed on extra-framework Al species, and, importantly, ammonia is stored in the form of ammonium ions NH\(_4\), by reaction with residual (not-exchanged) Brønsted sites.\(^{22}\) Very recently, Chen et al.\(^{27}\) used first principle calculations to propose a molecular level interpretation of NH\(_3\)-TPD measurements, supporting the presence of [Cu\(\text{II}\)(NH\(_3\))(OH)]\(^+\) species contributing to the two NH\(_3\)-TPD peaks observed below 200 °C and in the 250-350 °C range for Cu-CHA catalysts.\(^{28-30}\)

This work is thus set in the scientific discussion focused on the reduction half-cycle, concerning the reactivity of NH\(_3\) with Cu-CHA. The reduction of Cu\(^{\text{II}}\) to Cu\(^{\text{I}}\), forming the mobile [Cu\(\text{II}\)(NH\(_3\))\(_2\)]\(^+\), is almost complete at 200 °C in the presence of NO + NH\(_3\), while exposure to NH\(_3\) alone results in a mixture of NH\(_3\)-solvated Cu\(^{\text{II}}\) and Cu\(^{\text{I}}\) ions.\(^{13}\) This indicates that NH\(_3\) alone can act as a reducing agent, but not as efficient as the NO + NH\(_3\) combination. Starting from this observation, we explored the formation, thermal stability and reactivity of amino-complexes in \textit{in situ} XAS and Diffuse Reflectance UV-Vis-NIR (DR-UV-Vis-NIR) spectroscopy under different conditions. Namely, XAS measurements were carried out during NH\(_3\)-TPD experiments starting from Cu-CHA samples activated in oxidizing or inert conditions, that is starting from Cu\(^{\text{II}}\) or Cu\(^{\text{I}}\) ions, respectively (e1 and e2). Temperature Programmed Surface Reaction (TPSR) of the Cu-amino complexes formed on an O\(_2\)-activated sample was also followed in the presence of NO (experiment e3). The NH\(_3\) interaction and subsequent desorption/surface reaction was studied from 100 to 500 °C to obtain information on the low temperature reactivity of ammonia, and on the stability of Cu-amino complexes during the NH\(_3\)-TPD process. Moreover, Multivariate Curve Resolution (MCR) analysis\(^{31-33}\) was applied to extract the X-ray absorption near edge structure (XANES) signatures of the involved Cu-species.\(^{9,19}\) This allowed us to propose structural models of the involved species and decomposition intermediates, and to follow quantitatively their evolution as a function of temperature, catalyst pre-treatment and reaction atmosphere.

2. Experimental

2.1 Catalyst synthesis and compositional characteristics

The Cu-CHA zeolite (SSZ-13) catalyst investigated in this work was synthesized and characterized as described in our previous reports.\(^{6,12,36,37}\) The material has Cu/Al = 0.444 and Si/Al = 13.1, as determined by ICP-OES elemental analysis. As shown in previous works, the activated catalyst mostly contains redox-active Z[Cu\(\text{II}\)(OH)] species,\(^{6,12,36,37}\) charge-balanced at isolated 1Al exchange sites. Z[Cu\(^{\text{II}}\)]\(^+\) species, at paired 2Al exchange sites in 6MR are expected to represent a minor component (10-20% total Cu, depending on the specific pre-treatment conditions adopted), in line with the composition-dependent trends highlighted in the recent literature.\(^{7,9}\)

2.2 In \textit{in situ} XAS

2.2.1 Gas flow setup and conditions for \textit{in situ} XAS experiments. \textit{In situ} XAS experiments were carried out on the BM23 beamline\(^{38}\) of the European Synchrotron Radiation Facility (ESRF) using the Microtomo reactor cell,\(^{39}\) developed by the ESRF sample environment group. The Cu-CHA powder, in its hydrated form at RT in air, was pressed in a self-supporting wafer with mass optimized for XAS measurements in transmission mode (~100 mg, resulting in $\Delta \mu_x = 0.5$ with total absorption after the edge of $\mu_x = 2.5$) and fixed inside the reactor cell. The cell was connected to an \textit{ad hoc} gas flow setup, consisting of three main channels, each of them connected with stainless steel tubes to gas bottles with different composition, namely pure He, pure O\(_2\) and 1% NO/He. The total flow rate and the composition of the feed were adjusted by three mass flow controllers. The cell was also connected to a \textit{vacuum} line installed on the beamline. Such setup was necessary for the fast switching from flow to static configuration. After stopping the flow, it allowed evacuating the cell volume down to 10\(^{-5}\) mbar pressure by means of a turbomolecular pump, as well as dosing NH\(_3\) to the sample in static conditions. The sample temperature during \textit{in situ} experiments was controlled by the heating system integrated in the Microtomo cell. In this work, we performed three \textit{in situ} XAS experiments, herein referred to as e1, e2 and e3. The corresponding temperature profile and gaseous environment at the sample are schemed in Figure 1. In e1, the sample was activated at 400 °C (heating ramp 3 °C/min), and maintained at fixed
temperature for ca. 60 min. The activation was performed by flowing in the Micromeritics cell 100 ml/min 50% O₂/He (O₂-activation). The sample was subsequently cooled to 100 °C (10 °C/min) while keeping the same atmosphere as for the activation. Once the 100 °C temperature was reached, 50 mbar of pure NH₃ were dosed to the sample from the vacuum line (after switching the cell inlet to the vacuum line channel) and kept interacting with the catalyst for 10 min. The sample was subsequently flushed with 100 ml/min of He under isothermal conditions at 100 °C and monitored by time-dependent XAS data until no further changes were observed in the XANES. The final step of the experiment consisted in NH₃-TPD conducted in He from 100 to 500 °C (heating rate 5 °C/min). The catalyst was kept at 500 °C in the same TPD atmosphere until the XAS signal was stabilized. Experiment e1 was conducted under the same conditions as e1, but the catalyst was activated to 400 °C in vacuum (vacuum-activation). Experiment e3 was conducted as e1 (O₂-activation) but NH₃-TPD was replaced by TPSR in 1% NO/He.

2.2.2 XAS data acquisition and data reduction procedures. In situ Cu K-edge XAS were collected in transmission mode, using double-crystal Si(111) monochromator for the incident energy and ionization chambers to detect incident (I₀) and transmitted photons (I₁). A Cu foil was measured simultaneously with all the collected XAS spectra by means of a third ionization chamber (I₂), for energy calibration. 40, 41 The chambers were filled with a He/Ar mixture up to 2.2 bar with Ar partial pressure of 0.1 and 0.3 bar for I₀ and I₁,2 chambers, respectively. We monitored the evolution of the XAS signal as a function of time/temperature with faster acquisitions of ~6 min/scan (during the isothermal step at 100 °C) and 12 min/scan (during TPD/TPSR from 100 to 500 °C). Spectra were collected with a constant energy step in the XANES region (ΔE = 0.5 eV for 6-min scans and 0.3 eV for 12-min ones) and with a uniform sampling step in k-space (Δk = 0.05 Å⁻¹). The static states of the catalyst, reached after complete stabilization of the XAS signal at fixed temperature were probed by two consecutive higher-quality XAS scans (~40 min/scan), collected with a sampling step of ΔE = 0.3 eV in the XANES region and Δk = 0.035 Å⁻¹ in the EXAFS part. The data were collected up to 13 Å⁻¹ with acquisition time increasing quadratically with k from 1 to 4 s/point. For the data analysis, the μ(E) curves of these two scans were averaged.

All the acquired XAS scans were aligned using their respective Cu metal foil spectra detected by the I₂ ionization chamber. Normalization to unity edge jump and extraction of the χ(k) functions for the static scans were performed employing the Athena software from the Demeter package. 42 Fourier-transformed (FT-) EXAFS spectra were obtained from the k²-weighted data in the 2.4 – 12.4 Å⁻¹ k-range.

2.2.3 Cu K-edge XANES spectra of model systems and key spectroscopic fingerprints. Focusing on the interaction of Cu-CHA with NH₃, we initially adopted the [Cu II(NH₃)₄]²⁺ and [Cu I(NH₃)₂]⁺ complexes measured in aqueous solution as model systems for NH₃-solvated Cu° and Cu⁺ species (green and red lines, respectively, in Figure 2a,c). To guide the interpretation of in situ experiments, we also considered the dehydrated states of the catalyst, as characterized after O₂-activation and vacuum activation at 400 °C (blue and grey lines, respectively, in Figure 2a,c). For these model spectra, the principal XANES fingerprints of relevant Cu° and Cu⁺ species are highlighted by coloured rectangles in Figure 2a. 43–46

These include: (i) the weak dipole-forbidden pre-edge peak at ca. 8977 eV, arising from the 1s → 3d transition in d⁰ Cu° ions, which unambiguously fingerprints the presence of Cu° in the sample; (ii) the rising-edge peaks in the 8980–8985 eV range, assigned to 1s → 4p transitions in Cu° ions, 47, 48 showing high intensity for linear Cu° species such as the [Cu I(NH₃)₂]⁺ complex in Figure 2a; 35, 49 (iii) the rising-edge peaks in the 8985–8990 eV range, assigned to 1s → 4p transitions in both Cu° and Cu⁺ centres; (iv) the so-called ‘white-line’ peak (first resonance after the edge), centred around 9000 eV, which intensity is usually directly proportional to the first-shell coordination number.

2.2.4 XANES Linear Combination Fit (LCF) analysis of activated catalyst. Due to the difficulty in obtaining appropriate experimental references to model the XAS of Cu° and Cu⁺ species coordinated to the specific zeolite lattice, MCR-derived reference spectra are a viable alternative, which allow for an accurate quantification of Cu-speciation in activated Cu-zeolites. 7, 9–11, 50 To this aim, we exploited the results obtained in a previous study, 9 where we employed the MCR approach 31–33 to extract the XANES signatures of well-defined Cu-species present in Cu-CHA catalysts with different composition (Cu/Al and Si/Al) in the 0.1–0.6 and 5–29 ranges, respectively, synthesized with equivalent approaches as adopted for the Cu-CHA catalyst studied in this work) along the dehydration process. Once these curves have been obtained from the MCR-analysis and attributed to the chemical species on the basis of calculated XANES spectra from DFT-optimized model clusters, they can be employed as references spectra in a simple LCF model to investigate related systems. 5, 10, 51, 52 In particular, we considered the MCR-derived curves for the five Cu-species illustrated in Figure 4a, namely hydrated Cu°, under-coordinated hydrated Cu°, Z[Cu°(OH)], Z₂Cu⁺ and ZCu° species.
For a detailed discussion on the exact nature of the identified Cu-species, as well as on the limitations of the method in discriminating structurally-similar moieties (e.g. under-coordinated hydrated Cu\(^{II}\) with mixed \(\mathrm{O}_2\)/\(\mathrm{OH}_2\)/\(\mathrm{OH}^–\) ligands, or \(\mathrm{Z}_2\mathrm{Cu}^{II}\) formed in correspondence of different Al siting in the zeolite lattice), the interested reader is referred to the original work.\(^5\)

The experimental XANES, \(\mu^{\text{exp}}\) (E), collected after \(\mathrm{O}_2\)- and vacuum-activation at 400 °C were fitted as linear combinations of the five reference spectra, \(\mu^{\text{ref}}\) (E), i.e.: \(\mu^{\text{lcf}}\) (E) = \(\sum w_i \mu^{\text{ref}}_i\) (E), optimizing the weights \(w_i\) for each MCR-derived reference spectrum, imposing 0 \(\leq w_i \leq 1\) and \(\sum w_i = 1\).

XANES LCF analysis was performed using an in-house script written in Wofram Mathematica environment. After appropriate instructions for importing/interpolating experimental and reference curves, the linear combination fit is performed through the following code:

\[
\text{lcf}=\text{NonlinearModelFit}\left[\text{exp}\left\{\mathrm{w1}\times \text{IntR1}[\text{x}]+\mathrm{w2}\times \text{IntR2}[\text{x}]+\mathrm{w3}\times \text{IntR3}[\text{x}]+\mathrm{w4}\times \text{IntR4}[\text{x}]+\mathrm{w5}\times \text{IntR5}[\text{x}],\text{w1}+\text{w2}+\text{w3}+\text{w4}+\text{w5}==1,\{\text{w1},\text{w2},\text{w3},\text{w4},\text{w5}\},\text{x}\right\} ;\right]
\]

where: \(\text{lcf}\) = linear combination fit curve; \(\text{exp}\) = experimental spectrum; \(\text{IntRi}\)\(\text{x}\) = interpolated reference spectra; \(\text{wi}\): LCF weight for each interpolated reference spectra \(\text{IntRi}\).

### 2.2.5 XANES MCR analysis of in situ XAS after interaction with \(\text{NH}_3\)

MCR analysis of in situ XAS data was performed employing the Graphical User Interface (GUI) developed by Jaumot and co-workers,\(^32\) based on the MCR-Alternating Least Squares (MCR-ALS) algorithm,\(^53\) using Matlab R2011b. The analysis was performed simultaneously on the whole in situ XAS dataset collected in e1-e3 (globally 59 XANES scans). Here, Principal Component Analysis (PCA) indicated four Principal Components (PCs)\(^5\), based on the evaluation of the scree plot and of the abstract components (scores) for the dataset. The experimental spectra were analysed in the (8972–9022) eV energy range, resulting in 71 energy points. Initial spectra of the four PCs for the ALS routine were guessed by using the pure variable detection method (SIMPLISMA algorithm\(^54\)). ‘Soft’ constrains employed in the reconstruction included non-negativity for both pure spectra and concentration profiles and closure to 1 for concentration profiles (allowed due to the element selectivity of the XAS technique, probing only and all the Cu-species present in the sample). The MCR-ALS routine converged successfully after 47 iterations. A series of quality indicators for the MCR analysis are reported in Table 1.

### 2.3 In situ Diffuse Reflectance UV-Vis-NIR spectroscopy

The in situ UV-Vis-NIR spectra were recorded in the 2500-200 nm range (4000-50000 cm\(^{-1}\)) at 1 nm resolution (corresponding to 250 and 1.6 cm\(^{-1}\) at 50000 and 4000 cm\(^{-1}\), respectively) on a Varian Cary 5000 spectrophotometer, equipped with a R928 PMT UV-Vis detector and a cooled PbS photocell NIR detector. Spectra were collected with a Praying Mantis element, coupled with a low temperature (LT) reaction chamber. The sample was pelletized using a hydraulic press, successively crushed and sieved, and the fraction between 300 and 150 µm was selected for the measurement. The background was measured at room temperature (RT) using Teflon powder inserted in the same cell used for the measurements. Measurements were carried out from RT to 400 °C, flowing the desired gases with an ad hoc built gas flow set-up. The setup consisted of three channels, each of them connected to a specific gas bottle (pure He, pure \(\mathrm{O}_2\), 1.8% \(\text{NH}_3/\text{He}\)) and to a mass flow controller. The lines that lead to the reactor were heated to 130 °C to prevent water vapour or \(\text{NH}_3\) condensation.

The sample has been activated in pure \(\text{O}_2\) to 400 °C (50 ml/min, heating ramp 5°C/min) and maintained at 400 °C for 60 min. Successively, the temperature was lowered to 200 °C, keeping the \(\text{O}_2\) atmosphere, to prevent Cu self-reduction. Once reached the desired temperature, the sample was exposed to 1200 ppm \(\text{NH}_3/\text{He}\) (50 ml/min). The evolution of the system was followed until stabilization and subsequently during heating to 400 °C (heating ramp 5 °C/min) in the same gas feed. A single UV-Vis-NIR spectrum collection required 5 min; consecutive spectra correspond to a temperature increase of \(\Delta T = 25\) °C. Spectra are reported as relative reflectance (R%), defined as:

\[ R_{\%} = \frac{R_{\text{sample}}}{R_{\text{reference}}} \times 100 \]

### 3. Results and discussion

#### 3.1 Qualitative insights from in situ XAS

Figure 2 shows an overview of the results at key stages during experiments e1-e3, together with selected reference spectra helpful to guide the interpretation of the in situ XAS data. Cu K-edge XANES (Figure 2a,b) provides a wealth of fingerprints useful to identify oxidation state and coordination geometry of Cu ions.\(^41, 55, 56\) These can be readily interpreted based on several previous studies on Cu-zeolite catalysts, carried out in the context of both \(\text{NH}_3\)-SCR\(^8, 13, 16, 17, 23, 49, 57\) and methane-to-methanol conversion\(^7, 10, 58-61\). A summary of the relevant spectroscopic fingerprints can be found in Section 2.2.3.

A first observation is that, after interaction of the catalyst with \(\text{NH}_3\) at 100 °C and stabilization in He or 1% NO/He, a substantial fraction of the Cu exists in the form of linear Cu\(^{II}\) species, as indicated by the characteristic XANES peak at 8983 eV (Figure 2b). The absence of a well-defined second-shell peak in the FT-EXAFS (Figure 2d) is consistent with the formation of mobile Cu-species. Indeed, Single scattering paths involving the Al/Si atoms of the zeolite closer to the Cu centre lead to a well-defined second-shell peak in the FT-EXAFS spectra (grey shaded box in the 2.0-2.7 Å range in Figure 2c), which then indicates a coordination of the Cu to the zeolite framework.
treatment in vacuum,\textsuperscript{9, 35} favours the formation of NH\textsubscript{3}-solvated Cu species. Moreover, the presence of NO largely enhances the abundance of Cu species under comparable temperature and interaction times \textsuperscript{8, 13, 63}. Based on the qualitative comparison with the reference XANES spectrum in Figure 2a, most of the Cu occurs as [Cu(NH\textsubscript{3})\textsubscript{2}]\textsuperscript{+} species after 120 min from NH\textsubscript{3} adsorption in 1%NO/He already at 100 °C.

It is worth to highlight that a suppressed intensity of the EXAFS signal could be also caused by high structural and thermal disorder affecting framework-coordinated species (becoming especially important at T > 400 °C for Cu\textsuperscript{I} ions), as well as antiphase effects due to their characteristic coordination environment.\textsuperscript{6, 9} However, the similarity between XANES and EXAFS for Cu-CHA after interaction with NH\textsubscript{3} at 100 °C and the reference spectra for the [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+} and [Cu\textsuperscript{I}(NH\textsubscript{3})\textsubscript{2}]\textsuperscript{+} complexes strongly support Cu mobilization, in this case.

This is also in line with the recent theoretical study by Chen et al.,\textsuperscript{27} which reports that NH\textsubscript{3}-TPR experiments should be interpreted considering the NH\textsubscript{3} desorption energy from mobile Cu-amino complexes, rather than from framework-coordinated cations.

A second consideration concerns the Cu/Cu\textsuperscript{II} ratio upon stabilization after NH\textsubscript{3} adsorption at 100 °C, as a function of the different experimental conditions adopted in e1-e3. The intensity of the XANES Cu\textsuperscript{I} fingerprint peak at 8983 eV, which is an indication for the Cu\textsuperscript{I} fraction in the catalyst, follows the order: e1 < e2 < e3 (green, light blue and blue curves, respectively, in Figure 2b). Both the activation procedure and the presence of NO after NH\textsubscript{3} adsorption influence the average Cu oxidation state observed.

A higher abundance of framework-coordinated Cu\textsuperscript{I} species prior to NH\textsubscript{3} adsorption, as a consequence of the thermal...
Nonetheless, from the qualitative analysis of the XANES, it is clear that a different Cu species is formed, characterized by a rising-edge peak at 8983 eV broader and less intense with respect to the one observed for linear [Cu(NH$_3$)$_2$]$^{2+}$, as well as by a prominent resonance at 8989 eV. The trend in the intensity of the characteristic XANES features among the three experiments is the same observed as at 100 °C, with the most developed features observed in e3, in the presence of NO. The corresponding FT-EXAFS spectra (Figure 2d) show a broadened and dampened first-shell peak, while it is impossible to distinguish well-defined contributions at higher distance from the Cu-absorber. High temperature data collection (500 °C) causes an inherent damping of the EXAFS signal. Moreover, a large structural disorder of the Cu local environment is evident, consistent with the above-mentioned high mobility of Cu ions, even if coordinated to the zeolite framework.

To get further insights into the Cu-species present in the catalysts during e1-e3, we examined the time evolution of the XANES spectra, both as a function of time at 100 °C after NH$_3$ adsorption (Figure 3a,c,e), and as a function of temperature/time during TPD/TPSR (Figure 3b,d,f).

In the first step at 100 °C, time-resolved XANES indicated a quick mobilization by NH$_3$ of the Cu-ions in the catalyst. Already after ~10 min from NH$_3$ dosage, the characteristic XAS features of framework-coordinated Cu$^+$ and Cu$^+$ ions have disappeared, replaced by the spectral signatures of Cu-amino complexes.

Linear Cu$^+$ species, fingerprinted by the XANES peak at 8983 eV, are initially more abundant if the material is activated in vacuum (e2, Figure 3c). In this case, the subsequent intensity development of the 8983 eV peak as a function of time from NH$_3$ adsorption is limited. In the other two experiments - e1 and e3 - the catalyst prior to NH$_3$ dosage only contains a minor amount of ZCu$I$ species, while most of the Cu is in the +2 oxidation state. While the initial intensity of the 8983 eV peak after NH$_3$ adsorption is lower than in e2, it progressively increases with time, at a much faster rate under a 1% NO/He gas flow (e3).

In all the experiments, the temperature increase initially resulted in the development of the XANES features of linear Cu$^+$ at the expenses of NH$_3$-ligated Cu$^+$ moieties. However, as can be observed in Figure 3b,d,f, the evolution of the 8983 eV peak is not monotonous: after ca. 450 °C its intensity starts to decrease. Simultaneously, the broad peak at 8989 eV develops, pointing to further transformations involving the NH$_3$-derived Cu$^+$ complexes.

In the following section, we will elaborate the qualitative insights reported so far into a quantitative evaluation of Cu-speciation during e1-e3, by applying XANES LCF and MCR analysis to the time-dependent dataset in Figure 3.

3.2 Evaluation of Cu-speciation by XANES LCF and MCR analysis

3.2.1 Cu-speciation in the activated catalyst. Prior to examining the *in situ* data collected after interaction with NH$_3$, a first step in our analysis was to evaluate the Cu-speciation in the O$_2$- and vacuum-activated material. As detailed in Section 2.2.4, to this aim we used as references the MCR-derived spectra of the five Cu-species illustrated in Figure 4a, obtained in a previous study.

Figure 4b,c reports the percentages of Cu-species found after O$_2$- and vacuum-activation at 400 °C. The high quality of the LCF can be appreciated in Figure 4d,e, comparing experimental and best fit XANES spectra for the O$_2$- and vacuum-activated catalyst, resulting in R-factors as low as 1.1 x 10$^{-4}$ and 2.7 x 10$^{-4}$, respectively.

The O$_2$-activated state mostly contains Z[Cu$^{II}$(OH)] species, and similar species with the same tridentate coordination geometry as Z[Cu$^{II}$(OH)] (Figure 4, grey box), such as monocopper(II) superoxides Z[Cu$^{II}$O$_2$]$^+$. A small fraction of ZCu$I$ (17% total Cu) is found, which gives rise to the weak shoulder at 8983 eV in the XANES (see Figure 4d). About 9% of the Cu is present in under-coordinated Cu$^+$ aquo-complexes. Z$_2$Cu$^{III}$ species are not detected within the sensitivity of the method (ca. 5% total Cu).

**Figure 4.** (a) Molecular models of the five pure Cu-species considered in the LCF model; atom colour code: Cu, green; H, white; O, red, Si, grey; Al, yellow. (b, c) Pie charts illustrating Cu-speciation in the O$_2$- and the vacuum-activated catalyst at 400 °C, as estimated by XANES LCF analysis using as references the five pure spectra obtained by MCR analysis in ref. 9 for the Cu-species shown in part (a), using the same colour code; statistical LCF errors on the percentage of Cu-species are also indicated. (d, e) Comparison between experimental and best-fit spectra for (d) O$_2$- and (e) vacuum-activated Cu-CHA. The LCF residuals and the five scaled components are also reported.
Activation in vacuum leads to the formation of a substantial fraction of ZCu species (72% total Cu), indicating 'self-reduction' of redox-active Z[Cu\textsuperscript{II}(OH)] moieties.\textsuperscript{6, 8, 9, 45, 46, 64, 65} Nonetheless, at the experimental conditions adopted, we also observe 27% of Cu still in the form of Z[Cu\textsuperscript{II}(OH)] after 60 min in vacuum at 400 °C. Consistently with the LCF results for the O\textsubscript{2}-activated material, the fraction of Z\textsubscript{2}Cu\textsuperscript{II} ions in 6MR fall below the method detection limit also after vacuum-activation. The XANES spectra collected on the activated catalyst cooled to 100 °C just prior to NH\textsubscript{3} dosage shows only minor modifications (see Figure 3a,c). Thus, the Cu-speciation evaluated at 400 °C represents, under a reasonable approximation, the state of the Cu in the material before interaction with NH\textsubscript{3} at 100 °C.

3.2.2 Nature of NH\textsubscript{3}-derived Cu-species. To extract quantitative information on Cu-speciation in the catalyst during interaction with NH\textsubscript{3} and TPD/TPSR, we have applied the MCR method to the in situ XAS dataset reported in Figure 3. Previous studies have shown that XANES LCF based on measured spectra of the [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+} and the [Cu\textsuperscript{I}(NH\textsubscript{3})\textsubscript{2}]\textsuperscript{+} complexes (see Figure 2a) provides good estimates for the Cu oxidation state in the presence of NH\textsubscript{3}, NH\textsubscript{3}+NO, or an SCR reaction feed below 200 °C.\textsuperscript{3, 7, 8, 13, 14, 16, 23, 49, 66} However, as explained above, further structural and chemical transformations occur at higher temperatures, which cannot be described based on the solution-phase-like Cu\textsuperscript{I} and Cu\textsuperscript{II} amino complexes alone. Thus, we adopted the state-of-the-art MCR approach (see Section 2.2.5 for details) to assess the number and the nature of Cu-species present in the investigated Cu-CHA catalyst under the e1-e3 experimental conditions.

Figure 5 reports an overview of the MCR-results, in terms of 'pure' XANES spectra (Figure 5a) and concentration profiles (Figure 5c-e for e1-e3, respectively) of the four Cu-species identified by PCA. Considering the characteristic XANES features of the MCR spectra together with their correspondent time/temperature dependent dynamics, we connected the identified PCs with the four Cu-species illustrated in Figure 5b. We assign PC1 to a Cu\textsuperscript{I} species, exhibiting a XANES spectrum very similar to the one of [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+}. The weak peak in the Cu\textsuperscript{I} 1s→4p energy range observed in the PC1 MCR spectrum (blue asterisk in Figure 5a) is most likely an artefact of the reconstruction. Indeed, the absence of a time window where exclusively Cu\textsuperscript{I} species are present and the remarkable intensity of the Cu\textsuperscript{I} peak in PC3 and PC4, could cause a trace of this feature to be fictitiously embedded also in the PC1 MCR curve. Notably, the XANES features correspond to the ones observed for [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+}, characteristic of NH\textsubscript{3}-ligated Cu\textsuperscript{I} centers,\textsuperscript{67} but they are significantly broadened with respect to the solution-phase complex, the double component in the white-line peak being much less pronounced. In line with the strongly coordinating nature of NH\textsubscript{3} and previous valence-to-core X-ray emission spectroscopy (vtc-XES) results under low-temperature SCR conditions,\textsuperscript{23} all these evidences are consistent with NH\textsubscript{3}-solvated mixed-ligand Cu\textsuperscript{I} species, structurally similar to [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+} but having one of the four first-shell NH\textsubscript{3} ligands replaced by an O-containing moiety. Considering the Cu\textsuperscript{I} species present in the catalyst prior to NH\textsubscript{3} dosage (see Section 3.2.1), the possibilities consistent with XAS results are reported here below:

\begin{align*}
Z\text{[Cu\textsuperscript{II}(OH)]} + 3 \text{NH}_3 & \rightarrow Z\cdot\cdot\cdot[\text{Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{3}(OH)]} \quad (1) \\
Z\text{[Cu\textsuperscript{II}(OO\textsuperscript{-})]} + 3 \text{NH}_3 & \rightarrow Z\cdot\cdot\cdot[\text{Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{3}(OO\textsuperscript{-})}] \quad (2) \\
Z\text{Cu\textsuperscript{I}} + 4 \text{NH}_3 & \rightarrow Z\cdot\cdot\cdot[\text{Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]} \quad (3)
\end{align*}

where the symbol ‘⋯’ refers to mobile Cu-complexes electrostatically tethered to a Z or Z\textsubscript{2} exchange site of the zeolite, but without a chemical bond with the zeolitic framework. We expect a very minor contribution from Z\textsubscript{2}⋯[Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}], because no significant contribution of Z\textsubscript{2}Cu\textsuperscript{II} sites was detected in this specific Cu-CHA sample (Cu/Al = 0.444 and Si/Al = 13.1) after activation (see Section 3.2.1). Also, all the Cu-species formed in eqs. (1)-(3) are expected to show very similar XANES spectra, so that they can plausibly lump into a single PC: in all cases we are dealing with (pseudo-) square-planar-like Cu\textsuperscript{II} complexes. PC1 is consequently connected with [Cu\textsuperscript{II}(NH\textsubscript{3})(X)]\textsuperscript{n+} species, where X = NH\textsubscript{3} (n = 2), OH or OO\textsuperscript{-} (n = 1). Notably, [Cu\textsuperscript{II}(NH\textsubscript{3})(OH)]\textsuperscript{+} complexes have been envisaged as relevant species in recently proposed mechanisms for low-temperature NH\textsubscript{3}-SCR.\textsuperscript{8}

All the other PCs correspond to Cu\textsuperscript{I} species. Analysing the concentrations profiles in Figure 5c-e, it is clear that, upon increasing the temperature, the three Cu\textsuperscript{I} species form in the sequence PC3 → PC4 → PC2. The MCR spectrum of PC3 is in excellent agreement with the one of the [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+} model compound measured in the solution phase (Figure 5a, wine dashed curve). Thus, we assign PC3 to solution-phase-like [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+}. Such species could be firstly formed through NH\textsubscript{3} solvation of ZCu\textsubscript{I} species already present in the catalyst due to self-reduction during activation:

\begin{equation}
\text{ZCu\textsuperscript{I}} + 2 \text{NH}_3 \rightarrow Z\cdot\cdot\cdot[\text{Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]} \quad (4)
\end{equation}

PC4 shows a XANES spectrum similar the one assigned to the [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+} species. The sharp and intense peak at 8983 eV is diagnostic, also in this case, for a linear Cu\textsuperscript{II} species. However, the PC4 MCR curve differs in the white-line region, and shows a higher normalized absorption in the 8985-8992 eV range with respect to PC3 one. Z[Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}], formed by desorption of one NH\textsubscript{3} ligand from mobile [Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]\textsuperscript{2+} complexes, has been investigated by theory in a number of reports.\textsuperscript{15, 27, 35, 68} DFT models in 6MR predict a linear Cu\textsuperscript{II} complex coordinated to one framework O atom in the proximity of the charge-balancing Al site and to the residual NH\textsubscript{3} molecule, where Cu is significantly lifted from the zeolite ring plane. This geometry is in good agreement with the characteristic of the PC4 MCR spectrum, supporting its assignment to a [Z[Cu\textsuperscript{II}(NH\textsubscript{3})\textsubscript{4}]] species.
Finally, PC2, develops in all the experiments from T > 300 °C concomitantly to the decay in the population of Z[Cu\(\text{I}(\text{NH}_3)\)]\(^+\) (PC4). Its theoretical spectrum shows several resonances at energy positions comparable with what is observed after vacuum-activation at 400 °C. The relative intensity of the XANES features is however different, with a general enhancement of the rising-edge features to the expenses of the white-line intensity. Notably, the PC2 MCR spectrum is in excellent agreement with the one obtained from MCR-analysis of HERFD-XANES spectra collected on a Cu-CHA material with similar composition as used here (Si/Al = 12, Cu/Al = 0.5) upon activation in He at 500 °C.\(^{11}\) It is thus plausible to assign PC2 to ZCu\(\text{I}\) sites, formed upon complete desorption/consumption of NH\(_3\) ligands. The differences in the ZCu\(\text{I}\) XANES signature after vacuum-activation at 400 °C and after TPD/TPSR at 500 °C suggest a preferential population of one amongst the two sites – in 8MR and 6MR (see Figure 4a, red box) - previously proposed for Cu\(\text{I}\) ions in the CHA framework.\(^{6,9,12}\) The higher intensity of the XANES rising edge peak points to a more linear Cu\(\text{I}\) coordination geometry, and could thus indicate ZCu\(\text{I}\) to preferentially stabilize in 6MR rather than 8MR (O–Cu–O bond angles of 142° and 82° in 6MR and 8MR, respectively, according to DFT models in ref.\(^{6}\)). This assignment would also be in agreement with the computed energetics of ZCu\(\text{I}\) in the 6MR vs the 8MR.\(^{7,68}\) In this respect, we have performed preliminary EXAFS fits on the spectrum collected at 500 °C at the end of e3 (Figure 2d, purple curve), containing ca. 95% of PC2 according to MCR results in Figure 5e. EXAFS analysis indicated a first-shell of O\(_{\text{fw}}\) atoms with coordination number N\(_{\text{O}_{\text{fw}}} = 1.6 \pm 0.4\) and average bond distance \(<R_{\text{O}_{\text{fw}}}> = (1.93 \pm 0.02)\) Å, consistent with the DFT-optimized model of ZCu\(\text{I}\) in the 6MR (\(N_{\text{O}_{\text{fw}}} = 2\); \(<R_{\text{O}_{\text{fw}}}> = 1.96\) Å, Figure 5b, purple box). Unfortunately, it was impossible to obtain conclusive results on the subsequent coordination shells, due to the limited EXAFS data quality and the high level of thermal and structural disorder present under these conditions. Future experiments aiming at improved quality in the high k-space range would be decisive to get more accurate and reliable fitting results.

3.2.3 Dynamics and thermal stability of NH\(_3\)-derived Cu-species. Having identified the chemical nature of the four structural components in e1-e3, we can now analyse their dynamics in the view of the characteristic conditions adopted in the three experiments. Let us first consider e1 and e2 (Figure 5c,d), which provide us direct information on the thermal stability of NH\(_3\)-derived Cu-species in the catalyst. During the isothermal step at 100 °C, the Cu-speciation is dominated by a mixture of [Cu\(\text{I}(\text{NH}_3)_3(X)\)]\(^{+}\) (PC1) and [Cu\(\text{I}(\text{NH}_3)_2\)]\(^{+}\) (PC3). The initial Cu\(\text{I}/\text{Cu}\text{I}\) ratio correlates with Cu-

reaction chemistry & engineering

100 °C in He flow (24%) is higher than in the O₂-activated case to the one of PC3 (a linear Cu I species), due to the oxidation of ZCu I to Z[Cu II(OH)] in the Cu PC1 component, also causing an underestimation of the global catalyst cannot be excluded while cooling from 400 to 100 °C to the presence of moisture soaking catalyst, prior to NH₃ dosage in e2, due to traces of NH₃-TPD 400-500 °C range in NH₃-TPD experiments. These evidences reinforce our assignment of PC1 to a large majority of mixed-ligand Cu II moieties such as [Cu II(NH₃)₃(OH)]¹⁺, efficiently desorbing NH₃ before 350 °C. Driven by the relevance of mobile [Cu(NH₃)₃]²⁺ complexes in the low-temperature NH₃-SCR mechanism,14, 15, 71 we examined in more detail the temperature-dependent evolution of [Cu(NH₃)₄]²⁺ and 2Z(Cu(NH₃)₃). As summarized in Table 2, the [Cu(NH₃)₃]²⁺ concentration reach its maximum at 230 °C (hereafter, Tc MAX) in both e1 and e2. Afterwards, it decreases with temperature, arriving at concentration lower that 10% total Cu at 410 °C (hereafter, Tc<sup><100%</sup>). These values are in very good agreement with the theoretical NH₃ desorption peak from [Cu(NH₃)₃]²⁺ in Cu-CHA simulated from first principles by Chen et al., approximately ranging from 200 to 400 °C with maximum desorption at ca. 350 °C (see also last column in Table 2).

Tc MAX for the Z(Cu(NH₃)₃) species is also found at ca. 410 °C, matching the Tc<sup><100%</sup> for [Cu(NH₃)₄]²⁺ as expected in the case of a progressive transformation of the latter species into the first. Z(Cu(NH₃)₃) undergoes a slower decay with temperature, converting into NH₃-free ZCu species (PC2): at the end of both e1 and e2 (500 °C in He) its concentration levels off to 25-30 % total Cu. Also this results is consisted with the theoretical study cited above, which indicates desorption from Z(Cu(NH₃)₃) until ca. 550 °C, a temperature which is not reached in our experiments. Notice that certain differences in the Tc MAX estimated in this work and literature works could be related to the employed experimental set-up, using pelletized samples in a reactor cell characterized by a large dead volume and a not-passing-through gas flow. The Cu-speciation in e3, carried out in a 1% NO/He flow, follows the same trends outlined above. However, in line with a number of previous studies,8, 13, 63 the presence of NH₃ (in this case pre-adsorbed at Lewis and Brønsted acid sites in the catalyst) and gas-phase NO greatly favours the Cu II to Cu I reduction. Under the conditions of e3, ca. 80% of Cu is found as [Cu(NH₃)₄]²⁺ already at 100 °C. The presence of NO during the heating step also speed up the Z[Cu(NH₃)₃]²⁺ → Z(Cu(NH₃)₃) → ZCu I cascade conversion: both Tc MAX and Tc<sup><100%</sup> for NH₃-derived Cu I species lower significantly with respect to the values observed in e1 and e2 (Table 2).

Table 2. Key temperatures in the MCR concentration profiles of [Cu(NH₃)₄]²⁺ (PC3) and 2Z(Cu(NH₃)₃) [PC4] (Tc<sup>MAX</sup>, temperature corresponding to the maximum concentration detected; Tc<sup><100%</sup>: first temperature when a concentration < 10% total Cu is detected) during experiments e1, e2 and e3. The temperature ranges for the NH₃ desorption peaks simulated by Chen et al.27 are reported for comparison in the last column.

In summary, results from e1 demonstrate that NH$_3$ alone is capable to reduce Cu, but much less efficiently with respect the NH$_3$ + NO mixture (e3). Starting from the lowest temperature probed in this work, 100 °C, NH$_3$ first acts as a solvating ligand for the Cu ions, initially preserving their pristine activation-dependent oxidation state. Thus, a larger initial fraction of Cu$^{II}$ directly yields to a larger population of [Cu(NH$_3$)$_3$]$^+$ in fixed time/temperature frame. Conversely, NH$_3$ solvation of Cu$^{II}$ ions will firstly yield [Cu$^{II}$(NH$_3$)$_3$(X)]$^{n+}$ species, needing a further reduction step to form [Cu(NH$_3$)$_2$]$^+$. Consequently, the overall conversion cascade during NH$_3$-TPD proceeds more efficiently in the former case, providing a rational from the higher fraction of bare Cu$^{II}$ found in the final state of e2 (from vacuum-activation) with respect to e1 (from O$_2$-activation).

3.3 Complementary insights from in situ DR UV-Vis-NIR spectroscopy

DR UV-Vis-NIR spectroscopy was used as complementary technique to follow the reactivity of Cu$^{II}$ ions with NH$_3$. In particular, we were interested in providing additional evidences about the reducing ability of NH$_3$ towards Cu$^{II}$ ions obtained after O$_2$-activation, similarly to what observed in experiment e1. The assignment of the UV-Vis features in heterogeneous catalysts is usually not straightforward, even in structurally well-defined systems such as Cu-zeolites.$^7,72$ Both ligand field $d$-$d$ transitions and charge transfer (CT) can be strongly affected in both intensity and frequency by the nature of ligands and local symmetry of the metal ions. This implies that the spectroscopic fingerprint of Cu-CHA (the well-known quadruplet)$^{79}$ could be related to one of the proposed Cu$^{II}$ sites (Z[Cu$^{II}$(OH)$_2$], Z$_2$Cu$^{II}$ or Z[Cu$^{II}$(OO)$_2$]) or, more likely results from an overlap of bands originating from the three different structures. Moreover, we cannot exclude a contribution from Cu$^{II}$ ions involved in multicentric Cu-oxo complexes. $^7,73,74$

Notwithstanding this complexity, interesting pieces of information can be obtained by in situ measurements following the evolution of Cu$^{II}$ electronic transitions during the interaction with NH$_3$. On the other hand, the structures extracted with the MCR approach could be used for a more precise assignment of the observed features.

Figure 6 reports the spectra obtained during the isothermal exposure of the O$_2$-activated catalyst to 1200 ppm of NH$_3$ at 200 °C (Figure 6a) and during subsequent heating in the same gas feed (Figure 6b). The spectra are here plotted as R%, to avoid the possible artefacts connected to the use of the Kubelka-Munk function.$^{75,76}$ Ammonia was dosed on the O$_2$-activated catalyst (previously activated at 400 and cooled in O$_2$ at 200 °C), whose peculiar spectrum is reported as a dotted line in Figure 6a. The spectrum of the sample is dominated by a broad band with a quadruplet shape in the $d$-$d$ transition region, which is well documented in the literature for O$_2$-activated Cu-CHA.$^{34,36,73,77,78}$ Furthermore, a well-defined shoulder around 32000 cm$^{-1}$ is present in the low energy tail of the CT transition. An unambiguous attribution of this spectral component to a structurally defined Cu species is still an ongoing challenge. Indeed, different copper-oxo complexes – both monomeric and multimeric - might give rise to signals in this region.$^7,74,73,74$

Upon exposure to NH$_3$, we do observe changes in the entire spectral region. In the NIR region, the overtones and combination modes associated with the presence of adsorbed NH$_3$ and NH$_4^+$ species grow with exposure time. The intensity of the quadruplet $d$-$d$ feature is affected immediately, together with the 32000 cm$^{-1}$ shoulder. While prolonging NH$_3$ exposure, these features are transformed into a new one, which is still ascribable to Cu$^{II}$ ions, due to the presence of a band with $d$-$d$ character centred at 14100 cm$^{-1}$. Based on LCF analysis with measured [Cu$^{II}$(NH$_3$)$_3$]$^{2+}$ and [Cu$^{II}$(NH$_3$)$_2$]$^{+}$ references, NH$_3$ dosage at 200 °C on O$_2$-activated Cu-CHA has been reported to result in a mixture of Cu$^{II}$ and Cu$^{I}$ amino-complexes (roughly 75% and 25%, respectively).$^{13}$ Since closed-shell Cu$^{II}$ ions cannot be involved in $d$-$d$ transitions, the observed $d$-$d$ band at 14100 cm$^{-1}$ and CT transition at 31200 cm$^{-1}$ (measured at half height) are ascribable to the [Cu$^{II}$(NH$_3$)$_3$(X)]$^{n+}$ complexes predicted on the basis of the XAS analysis described above. Indeed, in aqueous solution [Cu$^{II}$(NH$_3$)$_4$]$^{2+}$ complexes are reported to absorb around 17000 cm$^{-1}$
cm$^{-1}$, while lower frequencies are found for [Cu$^{II}$(NH$_3$)$_2$]$^{+}$ with n<4, due to the insertion of H$_2$O/OH$^-$ ligands in the coordination sphere of the metal ion.$^{14}$ The mobilization of Cu$^{II}$ ions, passing from framework O atoms to NH$_3$ ligands, is also testified by the blue-shift of the CT transition. This is in fact expected to move to higher frequency by decreasing the optical electronegativity of the ligands.$^{30,81}$ The presence of water in the coordination sphere of Cu$^{II}$ ions can be safely discarded due to the absence of the overtone and combination modes of physisorbed water in the NIR region (not reported). The observed decrease in intensity in Figure 6a cannot be used for a quantitative estimation of the amount of reduced copper. Indeed, a change in the metal ion symmetry (passing from framework interacting ions to more symmetrical NH$_3$-solvated ones) is expected to decrease the corresponding extinction coefficient. Conversely, in agreement with XAS results, the spectra reported in Figure 6b provide evident indications of the concentration rise of Cu$^{I}$ species during the heating ramp to 400 °C, as indicated by the disappearance of bands in the d-d region. The reduction proceeds gradually with the temperature increase, with major changes above 300 °C. The final state reached at 400°C is that of a fully reduced catalyst (the peak at 10000 cm$^{-1}$ is an artefact due to bad background compensation), possibly with a mixture of [Cu$^I$(NH$_3$)$_3$]/Z[Cu$^I$(NH$_3$)$_2$] species. We cannot exclude a contribution also from ‘bare’ ZCu$^I$ sites.

This hypothesis is also confirmed by the blue-shift of the CT transitions (from 31200 to 35500 cm$^{-1}$), which is in agreement with the expected change passing from divalent to monoivalent metal centres. Moreover, the spectrum measured ex situ at RT after exposure to NH$_3$ at 400 °C (not reported) show CT band at higher frequency (39500 cm$^{-1}$). We can hypothesize that in these conditions [Cu$^I$(NH$_3$)$_3$] complexes are the main species, while at 400 °C a consistent fraction of framework interacting Z[Cu$^I$(NH$_3$)$_3$] sites is responsible for the observed red-shift.

These results nicely fit with the detailed XAS analysis described above. First, they confirm the occurrence of redox phenomena in a NH$_3$-only feed, favoured as temperature increases from 200 to 400 °C. Secondly, the observed positions of the d-d and CT absorption (also in comparison with reference data)$^{30,82}$ are in good agreement with the presence of mixed-ligand Cu$^I$ and Cu$^II$ amino moieties.

4. Conclusions

In this work we explored by in situ XAS and UV-Vis-NIR spectroscopy the nature and thermal stability of NH$_3$-derived Cu$^I$ and Cu$^II$ species in an industrially-relevant Cu-CHA deNO$x$ catalyst. Both the techniques confirm a fast and complete ‘solvation’ by NH$_3$ of the framework-coordinated Cu$^I$ ions formed upon thermal activation of the catalyst. Interaction with NH$_3$ in the 100-200 °C range drives the Cu in the material in a quasi-mobile state (Cu$^I$ and Cu$^II$-amino complexes fully detached from the framework, but electrostatically tethered to charge-balancing exchange sites in the zeolite). All our spectroscopic evidences indicate that NH$_3$ desorption at T > 200 °C is accompanied by Cu$^II$ → Cu$^I$ reduction phenomena, also in the absence of NO. In line with previous reports, the simultaneous presence of NH$_3$ (pre-adsorbed and/or in the gas phase) and gas-phase NO largely enhances and speeds up the reduction effect. Notice that this is at variance with respect to XAS/XES observations in the presence of the whole SCR mixture, pointing to the formation of a dominant fraction of framework interacting Cu$^{II}$ ions above 250°C.$^{23}$ These insights corroborate some of the most innovative concepts developed in the last years in the field of NH$_3$-SCR over Cu-zeolite catalysts, that are the impact of reaction conditions on the nature of the Cu-species present, as well as the relevance of Z-[Cu$^I$(NH$_3$)$_2$] species in the low-temperature reaction mechanism.$^{7}$

Aiming to achieve a deeper understanding of the NH$_3$-derived Cu-species formed in Cu-CHA, in this work we have applied MCR analysis to extract quantitative information from in situ XANES data. Despite some inherent limitations of the method, this statistical/chemometric approach allowed us to access a much higher level of detail with respect to LCF analysis using experimental spectra of [Cu$^I$(NH$_3$)$_3$]$^+$ and [Cu$^II$(NH$_3$)$_4$]$^{2+}$ model compounds. The MCR results, providing ‘pure’ spectra and concentration profiles of the Cu-species present during in situ XAS experiments, are interpreted in comparison to experimental and theoretical reports focusing on NH$_3$-TPD profiles for Cu-CHA.$^{27-30}$

The most relevant points emerging from MCR analysis include: (i) formation of mixed-ligand amino-Cu$^I$ moieties such as Z-[Cu$^I$(NH$_3$)$_3$(OH)]$_{1-3}$ undergoing NH$_3$ desorption from temperatures as low as 100 °C; (ii) experimental validation of the temperature range for NH$_3$ desorption from Z-[Cu$^I$(NH$_3$)$_3$]$_n$, identified here as 230-410 °C, in agreement with the computational prediction by Chen et al.$^{79}$; (iii) deconvolution of the contributions from quasi-mobile Z-[Cu$^I$(NH$_3$)$_3$] and framework-coordinated Z[Cu$^I$(NH$_3$)$_3$] and isolation of the XANES spectrum of the latter species; (iv) structural sensitivity of the final NH$_3$ desorption step Z[Cu$^I$(NH$_3$)] → ZCu$^I$ + NH$_3$ and possible preferences for 6MR sites.

Notably, the possibility to discriminate by XANES the structurally similar Z-[Cu$^I$(NH$_3$)$_3$] and Z[Cu$^I$(NH$_3$)$_3$] species is crucial to accurately determine by XAS the transition from quasi-mobile species - capable of O$_2$-activation by transient pair formation$^{14,15,71}$ to ‘immobile’ Z[Cu$^I$(NH$_3$)$_3$] species with O$_{oxe}$-Cu$^II$-NH$_3$ ligation. As also observed by Chen et al.$^{79}$ based on simulated NH$_3$-TPD profiles, the concentration rise of Z[Cu$^I$(NH$_3$)$_3$] well corresponds to the dip in NO conversion often observed in the 300-350 °C range for NH$_3$-SCR over Cu-CHA catalysts. O$_2$-activation over this intermediate, demarking the transition from low- and high-temperature SCR regimes, is indeed likely hampered with respect to ‘bare’ ZCu$^I$, due to the residual NH$_3$-ligand.

Overall, the information obtained here expands the fundamental knowledge basis required to unravel the NH$_3$-SCR mechanism over Cu-CHA, across the whole temperature range of interest for industrial applications. Future studies in this direction could exploit the pure MCR spectra obtained here
and further validate our assignments by DFT-assisted XANES simulations of the proposed Cu-species.

Acknowledgements
CL acknowledges the Mega-grant of the Russian Federation Government to support scientific research at the Southern Federal University, No. 14.Y26.31.0001. We are grateful to Filippo Giordano for his contribution in designing and performing the XAS experiments and to Haldor Topsøe A/S for financial support to his Ph.D. project. We also thank Andrea Lazzarini for support during the XAS data collection, Andrea Martini for programming the script for XANES LCF and for support in the interpretation of the results, Olivier Mathon for his competent assistance during the XAS measurements on the BM23 beamline of the ESRF. We are grateful to Silvia Bordiga for insightful advices and constant scientific support.

In situ XAS and UV-Vis-NIR spectroscopy shed light on Cu-speciation during NH$_3$ temperature-programmed desorption and surface reaction (TPSR) over a commercial Cu-chabazite deNO$_x$ catalyst, expanding the fundamental knowledge required to unravel the NH$_3$-SCR mechanism across the whole operation-relevant temperature range.
